Aftershock Observations of the 1999 Chi-Chi, Taiwan Earthquake

Naoshi Hirata¹⁾, Shin'ichi Sakai¹⁾, Zen-Sen Liaw²⁾, Yi-Ben Tsai²⁾ and Shui-Beih Yu³⁾

Abstract

We conducted aftershock observations of 20 September, 1999 Chi-Chi, Taiwan Earthquake beginning 15 days after the main shock. We deployed 20 seismographs twice in a 100 km by 100 km area around the focal area of the main shock. Each observation period lasted one month. Two months of observations yielded about 80 GB of continuously recorded aftershock data, from which a large number of aftershocks are identified. Among these we located 736 aftershocks from a four-day record. Taking lateral heterogeneity in the crustal structure into account, we have a clear distribution of the aftershocks. There are three particular trends in the east-west cross-section: an east-dipping plane, a nearly flat plane distribution, and a deeper cluster. These trends correspond to the fault plane of the main shock, the hypothesized decollement between the accretionary wedge, and the upper boundary of the Eurasian Plate, and intra-plate activity respectively.

Key words: Chi-Chi Taiwan earthquake, aftershock distribution, temporary observation, decollement

1. Introduction

On September 20, 1999 UT (September 21 Local time), an earthquake with a local magnitude of (M_L) 7.3 (Ms=7.7) occurred in central Taiwan. The Island of Taiwan is located on the boundary between the Eurasian and Philippine Sea plates; the two plates either collide with each other or one plate is being subducted (Fig. 1). The Eurasian Plate is subducting eastward beneath the Philippine Sea Plate in southern Taiwan. In northern Taiwan, the Philippine Sea Plate is subducting northward beneath the Eurasian Plate at the Ryukyu Trench. In central of Taiwan, there is a collision boundary between the two plates (Seno, 1994). The location of the boundary in middle Taiwan is not well defined: one possibility is that the boundary lies in western Taiwan, eastern bounds of the foothill plain, and the other is that the Longitudinal Valley in eastern Taiwan is the plate boundary. The convergence rate of 7.1 cm/y between the two plates (Seno et al, 1993) is rapid and the central mountain range of Taiwan has a high erosion rate of 5.5 cm/y (Li, 1975).

The earthquake, named for the nearby town of Chi-Chi, was followed by numer-

ous aftershocks including five large aftershocks with a local magnitude (M_L) of 6.0 or more in one week. Through November 8, eight large aftershocks $(M_L \ge 6)$ occurred in and around the focal area, including the November 2, 1999, earthquake $(M_L = 6.9)$ southeast off Hualien city. The aftershock area extends about 100 km in both the north-south and east-west directions (Fig.2). The aftershock activity seems to coincide with the area of active background seismicity of central Taiwan. The eastern limit of the aftershocks lies at the boundary between the seismically active and the inactive areas beneath the central mountains.

In Taiwan, 75 telemetered seismic stations are operated by the Central Weather Bureau (CWB) (Wu et al., 1997). Although the station spacing of this seismic network is sufficient to monitor felt earthquakes, detailed spatial distributions of the aftershock activity are not well constrained by the CWB data. Ten stations are located in the vicinity of the focal area, but some of them were damaged by the main shock, and were not available for the aftershock study. To understand the detailed aftershock distribution in space and time, we deployed 20 temporary seismic stations in the 100 km by 100 km focal area beginning 15 days after the main shock.

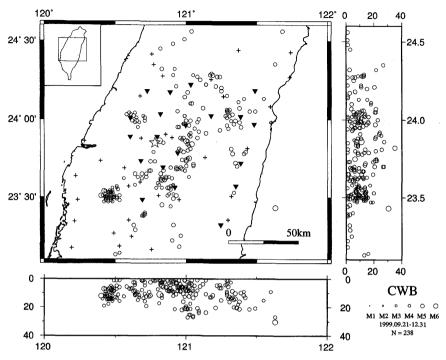

Fig. 2. Aftershock distribution from September 21 to December 31, 1999 reported by the Taiwan Central Weather Bureau. Data are from a web page of the CWB (http://www.cwb.gov.tw/). The star indicates the location of the mainshock.

2. Observation

We started to deploy 20 temporary seismic stations on October 5, 15 days after the main shock. The stations are distributed between permanent seismic stations operated by the CWB (Fig. 1). We designed the configuration of the temporary stations so that both the permanent and the temporary networks complement each other.

Each temporary seismic station consists of a 3-component, 1-Hz seismometer, a 16-bit digital recorder operating at a sampling rate of 100 Hz and a GPS receiver for timing (Shinohara *et al.*, 1997). The GPS data were recorded every four hours. The battery-powered recorders ran continuously for 40 days, and we re-deployed the seismographs in mid-November to continue observations until the mid-December. Some seismic stations were installed in public schools or temples in small towns and the others were along roads. One of the stations, TJ09, was located near the Chelungpu Fault (Photos 1,2,3). Locations and periods of operation of each temporary seismic station are listed in Table 1.

Three persons from the Earthquake Research Institute (ERI) visited Taiwan for two weeks to deploy the seismographs, and one seismologist from Taiwan National

Photo 3.

Central University participated in the deployment. For the second deployment, one seismologist and two technicians visited Taiwan from ERI. The instruments were retrieved by two technicians from ERI and one assistant acting as an interpreter from the Institute of Earth Science, Academia Sinica. The personnel are tabulated in the Appendix.

3. Data Processing

Because we recorded ground motion continuously, we processed the data for editing after the observations. We obtained about 80 GB of digital records in total. We first decompressed the original field data, which are compressed at recording, and converted them into the win format (Urabe, 1994) routinely used in the Earthquake Research Institute for telemetered seismic observations. During decompression we used the GPS data to calibrate the internal clock of the recorder. The corrected data have a timing error of 1 ms or less, which is sufficient for phase picking.

During conversion into the win format we multiplexed the data from all stations to have a common time base. We detected seismic events on the multiplexed data to make event files. The event files were scanned by an automated phase picker to get *P*- and *S*-wave arrival times. We examined all event files again by eye to confirm whether the automatically picked phase data were correct or not, especially for

S-phase pickings. Because the aftershock activity was very high, with aftershocks occurring almost every 10 s (Fig. 3), we first processed the data from the first four days to see the spatial distribution of the aftershocks. We present preliminary results for the first four days of data in this report.

4. Analysis

We located 736 aftershocks during the period from October 11 to 14, 1999. The total number of aftershocks in this period is greater than those we located, because at this stage we have not processed the entire record. We first tried to locate the aftershocks using the one-dimensional velocity model (Fig. 4) used by the CWB (Chen, Y.L., 1995). The resulting distribution shown in Fig. 5 is nearly the same as that reported by the CWB (Fig. 1).

We found a systematic residual in travel times for each station by carrying out an iterative analysis of station delays and hypocenters. First, we located aftershocks and calculated the mean residual arrival times for *P*- and *S*-waves at every station. We then used these values for station correction, relocated the hypocenters,

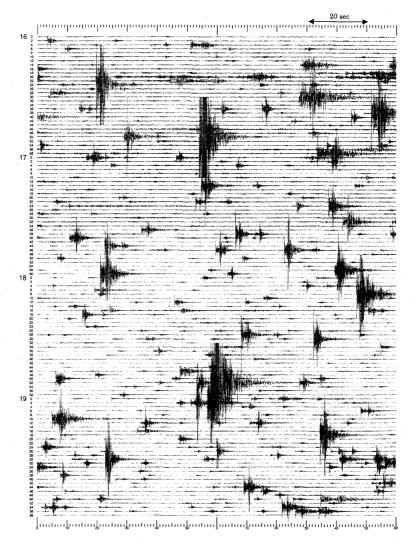

Fig. 3. Example of the waveform data from the aftershocks. Continuous seismic data for $4\,\mathrm{hrs}$ recorded at station TJ10 are shown (Oct. 12. 16: 00–20: 00. UT).

and computed new station corrections. We repeated the procedure several times until we got almost identical hypocentral distributions after iteration. We have relatively large final station corrections for both P- and S arrivals, suggesting lateral heterogeneity in the crust. The estimated station corrections are listed in Table 1. More detailed studies of the crustal heterogeneity will appear elsewhere.

5. Results

We show hypocenters of the aftershocks with station corrections in Fig. 6. The microseismic activity is distributed in an area of 100 km in both the north-south and

east-west directions. The western boundary of the seismicity coincides in general with the surface trace of the Chelungpu fault, but there is minor activity west of the fault. Within the area are several clusters. Some of them occurred immediately after the main shock and the other started to be active since October 22, 1999. The former includes the cluster near Fenyuan (Station TJ13) and the latter comprises aftershocks of the M_L =6.4 earthquake near Chiayi.

The east-west cross section shows three particular trends in the distribution of hypocenters. The first is an east-dipping distribution with a dip angle of about 30 degrees. The trend projects to the surface at the Chelungpu Fault. The strike and the dip of this aftershock trend are consistent with the focal mechanism of the main shock (Kikuchi and Yamanaka, 1999). The second trend is a very low angle or almost flat cluster at a depth of about 10 km. From the east-west profile in Fig. 6, the flat and the east-dipping distributions seem to intersect each other. However, in a horizontal section, the flat activity is located in the northern area and the east dipping trend lies in the middle to southern area of the aftershocks. The third cluster lies at depths from 20 to 30 km, apparently deeper than the other clusters and 20 km east of the main shock.

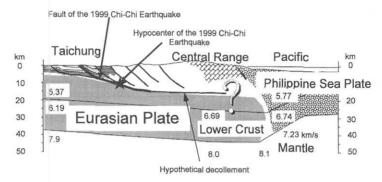

Fig. 7. Schematic model for the crustal structure of Taiwan and the 1999 Chi-Chi, Taiwan, Earthquake. Numbers are P-wave velocities in km/s from Shih et al. (1998).

6. Discussion

In western Taiwan a west-vergent thrust system is well developed with a NS strike parallel to that of the Island of Taiwan itself. This fold-and-thrust belt mainly deforms late Tertiary sedimentary rocks. The collision tectonics started in the Pliocene, and the area has suffered an intense shortening deformation (Page and Suppe, 1981). The geologic structure is characterized by a well-developed fold-and-thrust belt very similar to that found along the trench slope of subducted plate (Fig. 7). Sedimentary material has been thickened by thrusting due to the eastward subduction of the Eurasian Plate. The westward migration of the thrust front is well recorded in the sedimentary successions in western Taiwan.

The preliminary analysis of the aftershock activity suggests that the 1999 Chi-Chi, Taiwan Earthquake occurred along the base of the accreted material and cuts to the surface on a thrust fault (Suppe, 1981, Sato and Hirata, 1999). We observed active seismicity at a depth of 10 km, which may correspond to the decollement between the Eurasian Plate and the accretionary wedge (Fig. 7).

According to a teleseismic study, the Chi-Chi Earthquake has a seismic moment M_o of $2.4\times10^{20}\,\mathrm{Nm}$ (Mw=7.5) and an average stress drop of 3.3 MPa with an assumed fault area of $80\times40\,\mathrm{km^2}$ (Kikuchi and Yamanaka, 1999). The estimated stress drop, $\Delta\sigma$, is smaller than that of a typical inland earthquake such as the 1995 Hyogokennanbu, Kobe, Earthquake ($\Delta\sigma{=}10\,\mathrm{MPa}$), but is similar to that of the plate boundary earthquakes that occur in trench areas. Because the average stress drop, $\Delta\sigma{=}2.5\,\mathrm{M}_o/\mathrm{S}^{1.5}$, where S is the area of the fault, depends on both M_o and S, if S is larger than that used for their estimate, then $\Delta\sigma$ can be smaller. The small $\Delta\sigma$ suggests that the Chi-Chi earthquake has similar characteristics to that of a plate boundary earthquake near the oceanic trench. Moreover, Seno (2000) claims that the Chi-Chi earthquake is a subduction zone earthquake.

There have been several large earthquakes in Taiwan in this century, including the 1906 Chiayi Earthquake (Ms=6.8) and the 1935 Taichung Earthquake (Ms=7.1),

between which the Chi-Chi earthquake occurred. To fully understand the tectonics that generated the Chi-Chi earthquake, we will need to synthesize both seismic and geodetic observations, especially data from recent GPS observations (e.g., Yu *et al.*, 1997).

7. Conclusions

We conducted aftershock observations for the 1999 Chi-Chi, Taiwan Earthquake for two months. We deployed 20 seismic stations in and around the focal area of the main shock. We continuously recorded ground velocity and later extracted the aftershock records. We analyzed 736 aftershock records, from which a distribution of the aftershock hypocenters was derived. Taking lateral heterogeneity of the crustal structure into account, we obtained clear depth distributions of the hypocenters. The east-dipping distribution is consistent with the fault plane solution of the main shock. A flat or very low angle distribution of seismicity coincides with the hypothesized decollement between the accretionary wedge and the upper boundary of the Eurasian Plate. The data we obtained may provide key information to help understand the tectonic processes that generate large earthquakes at convergent plate boundaries.

Acknowledgments

The present study was conducted using five different funds so that aftershock observations could be started as soon as possible. Partial support came from the Japan-US Joint Research Project of the Japan Society for the Promotion of Science (Structure, Seismicity and Tectonics of the Japanese Island arc from new deep seismic exploration, EPAR-163/97-26766), a Grant-in-Aid for Specially Promoted Research (No. 11800012) of the Japan Ministry of Education, Science, Sports and Culture, and Grant-in-Aid for Scientific Research (No. 10640400).

We were also supported by the Short-term Oversea Research Program of the Ministry of Education, Science, Culture and Sports and the Research expenses of the Earthquake Research Institute.

We thank Dr. Yhi-Hsiung Yeh, Director of Institute of Earth Sciences, Academia Sinica, for providing logistical and scientific help to complete our study in Taiwan. Izumi Ogino and Masaru Kobayashi helped us to deploy and retrieve the seismographs and processed the field data in preparation for analysis at ERI. We thank our driver, Wang, from IESAS and Keng-Sheng Su for being our guide and interpreter.

Appendix

The present study is part of the Japan-Taiwan Cooperative Research Program, which was organized after the 1999 Chi-Chi, Taiwan Earthquake. The research includes a mission from Japan to Taiwan in 1999 and 2000. The following were members of the mission group from Japan.

(i) Principal Investigator

Naoshi Hirata (the Earthquake Research Institute, the University of Tokyo, Seismology)

(ii) Geomorphology

Kenshiro Ohtsuki (Graduate School of Tohoku University, Geology)

Yasutaka Ikeda (Graduate School of the University of Tokyo, Geomorphology)

Hiroshi Sato (Earthquake Research Institute, the University of Tokyo, Geology)

(iii) After-effects on the crustal activity

Shin'ichi Sakai (Earthquake Research Institute, the University of Tokyo, Seismology)

Shigeru Nakao (Earthquake Research Institute, the University of Tokyo, Geodesy)

Izumi Ogino (Earthquake Research Institute, the University of Tokyo, Seismology)

Masaru Kobayashi (Earthquake Research Institute, the University of Tokyo, Seismology)

Yasuhiro Hirata (Earthquake Research Institute, the University of Tokyo, Geodesy)

(iv) Seismotectonics

Tetsuzo Seno (Earthquake Research Institute, the University of Tokyo, Tectonics)

1999 年台湾集集地震の余震観測

1999 年 9 月 21 日 (現地時間) に台湾で起きた集集地震の臨時余震観測を行なった. 震源断層面を取り囲むように、100 km 四方の領域に 20 点の観測点を配置した. 観測は、DATに連続記録を収録する方式で、乾電池で約 1 ヶ月間稼働することができる. 本震発生 2 週間後の 10 月 7 日から 12 月 22 日まで観測を行ない、数多くの余震を観測した. このうち初期の 4 日間のデータを再生し、736 個の余震の震源決定を行なった. 地殻の速度構造の不均質を考慮した観測点補正値を導入し、詳細な震源分布を得た. 東下がりの余震分布は本震の震源断層面を表し、ほぼ水平な分布は付加帯とユーラシアプレートとの境界面であるデコルマ、そしてより深部の分布はプレート内で発生した地震を表している.
