

12. *Determination of Origin Times, Epicenters and
Focal Depths of Aftershocks of the Niigata
Earthquake of June 16, 1964.*

—A Preliminary Report of the Cooperative
Study of Aftershocks of the
Niigata Earthquake—

By Ichiro KAYANO,

Earthquake Research Institute.

(Read Sept. 27, 1966.—Received Jan. 26, 1968.)

1. Introduction

A destructive earthquake occurred near the coast of Niigata Prefecture, the northern part of central Honshu, Japan, on June 16, 1964.

After the earthquake, field parties were dispatched for aftershock observation from Hokkaido University¹⁾, Tohoku University, the Earthquake Research Institute of the University of Tokyo²⁾ and the Japan Meteorological Agency (JMA)³⁾.

Two to four parties were sent from each organization and some results obtained by them have been reported in their respective papers. However, it was considered to be most effective to analyse these observational data with the cooperation of all the parties participating in the field observation.

As the first step for further investigation of aftershocks of the Niigata Earthquake, the author was asked to collect all the data from each of the parties in order to undertake preliminary determination of origin times, epicenters and focal depths of the aftershocks.

On the basis of these data, the author carried out epicentral determination by several different methods and studied how the results are

affected by the method of determination adopted.

This paper is a report of such work undertaken by the author and is published with the consent of all the members of the participating parties.

2. Data

The locations of temporary observation stations, the instruments used and the periods of observation are given in Table 1 and the distribution of the stations is indicated in Fig. 1.

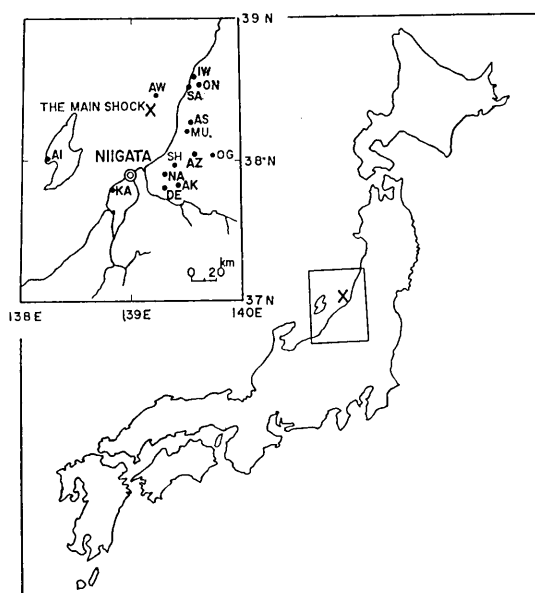

Fig. 1. Distribution of the temporary observation stations.

Making up for the lack of observation station to the north and the west of the aftershock region, the seismometrical data obtained at Aikawa Weather Bureau belonging to JMA were used together when available, through the courtesy of JMA. However, shocks of smaller magnitude were not recorded at this bureau due to low sensitivity of the seismographs installed there.⁴⁾

Epicentral determination of the aftershocks was done for the period of fourteen days, from June 23 to July 6, when most of the temporary stations were in operation.

Arrival times of the *P* and *S* waves and/or *P-S* intervals at each station, which were read off by the members of each party, were sent to the Earthquake Research Institute and were compiled as "Collected Data of Temporary Observation of Aftershocks of the Niigata Earthquake".⁵⁾ Since the Type-59 Electromagnetic Seismograph was not used in routine work at Aikawa Weather Bureau, its seismograms were read off by the members of the

4) The Seismological Bulletin of the Japan Meteorological Agency.

5) This table was distributed among the members of the participating parties in blue print.

Earthquake Research Institute.

Time accuracy was kept within ± 0.1 sec at each station.

3. Determination of origin times, epicenters and focal depths.

On the basis of the data collected in the table mentioned above, origin times, epicenters and focal depths were determined.

For the sake of convenience, a Cartesian coordinate system is used taking the origin at $37^\circ 45'N$ and $139^\circ 15'E$, x eastward, y northward and z downward, and the kilometer as the unit of length.

In the present paper, a homogeneous half space is assumed.

3.1. Determination of origin times, epicenters and focal depths from arrival times of the P wave.

At the first step, origin times, epicenters and focal depths were determined using only arrival times of the initial P wave at each station.

The relation between hypocenter, observation station, arrival time and the wave velocity is expressed as follows:

$$(1) \quad (x-x_i)^2 + (y-y_i)^2 + (z-z_i)^2 = v^2(t-t_i)^2, \quad i=1, 2, \dots, N,$$

where

- x, y, z : coordinates of a hypocenter
- t : origin time
- x_i, y_i, z_i : coordinates of an observation station
- t_i : arrival time
- v : wave velocity
- N : number of observation data.

If we put

$$x = x' + \Delta x, \quad y = y' + \Delta y, \quad z = z' + \Delta z, \quad t = t' + \Delta t, \quad v = v' + \Delta v, \\ r_i^2 = (x-x_i)^2 + (y-y_i)^2 + (z-z_i)^2,$$

where x', y', z', t' , and v' are trial solutions and $\Delta x, \Delta y, \Delta z, \Delta t$ and Δv are corrections to be added to them, we can linearize equation (1) as follows, neglecting terms of higher order,

$$(2) \quad \frac{x'-x_i}{v'r'_i} \Delta x + \frac{y'-y_i}{v'r'_i} \Delta y + \frac{z'-z_i}{v'r'_i} \Delta z + \Delta t - \frac{r'_i}{v'^2} \Delta v = t_i - \left(\frac{r'_i}{v'} + t' \right).$$

If $x' + \Delta x$, $y' + \Delta y$, $z' + \Delta z$, $t' + \Delta t$ and $v' + \Delta v$ are substituted into x' , y' , z' , t' , and v' in the next step, then x, y, z, t and v are expected to converge to some finite values after several iterations.

Observation data t_i is weighted with

$$p_i = \frac{\sigma_i^2}{\sigma_0^2},$$

where σ_i is the standard error of t_i , σ_0 is the standard error of the value with a unit weight, which may be an arbitrary value in the beginning of the procedure and in the present paper is assumed to be 1.0 sec. Strictly speaking, σ_i must be different for each observation, but it is practically impossible to estimate the value of σ_i individually. Then σ_i is assumed to be 0.1 sec for iP , 0.2 sec for P and 0.3 sec for eP . At the end of the process, σ_0 can be estimated as follows:

$$\hat{\sigma}_0 = \sqrt{\frac{S}{N-m}},$$

where

S : weighted sum of squares of residuals,

i.e. $S = \sum p_i \varepsilon_i^2$, where $\varepsilon_i = t_i - \left(\frac{r_i}{v} + t \right)$,

m : number of unknowns.

The starting point of the first iteration was chosen at $x=0$, $y=60$ and $z=30$ in all cases. Iteration was stopped when the condition $\Delta x^2 + \Delta y^2 + \Delta z^2 \leq 0.01 \text{ km}^2$ was satisfied, usually after three or four iterations.

For the shock of which arrival time of the P wave was observed at five or more stations, calculation was carried out letting x, y, z, t and v unknown, but in most cases reasonable solution was not able to be obtained. In some cases, solutions did not converge and in some cases depths and/or wave velocity resulted in unreasonable value.

In the course of iteration, the depth z often became negative. Then z was assumed to be 5 km (0 km in some cases), because the foci in such cases are considered to be very shallow.

The calculation was carried out for some thirty cases taking trially five values of the velocity, 4.5, 5.0, 5.5, 6.0 and 6.5 km/s. The smaller velocity makes the focus deeper and the origin time earlier, because the

smaller velocity lessen the differences between hypocentral distances. On the other hand, the larger velocity makes the focus shallower, while too large a velocity makes the depth impossible to be determined. The value 6.5 km/s for the velocity seems to be too large for the solution to be obtained. In many cases the velocity 4.5 or 6.5 km/s gave the minimum residual, while the velocity 5.0, 5.5 and 6.0 km/s rarely gave the minimum residual. As a trial, hypocenters were determined by the use of P - S intervals obtained at three or more stations and it is found that the depths of foci of most aftershocks are distributed between 20 km and 30 km⁶⁾ and the average velocity at depths shallower than 30 km is of value between 5.5 and 6.0 km/s. The value of velocity that gives the minimum residual is not necessarily the best approximation of the velocity, because it is apt to be greatly influenced by observational errors.

Considering these matters, the velocity 6.0 km/s was adopted and origin times, epicenters and focal depths of some 300 aftershocks were determined.

In order to examine the result, $\hat{\sigma}_0$, which is a measure of accuracy of observation, was checked. The distribution of $\hat{\sigma}_0$ is shown in Fig. 2(a). $\hat{\sigma}_0=1$ means that residuals are as large as observational errors assumed in the beginning, that is, for example, 0.1 sec for iP . In the case of which $\hat{\sigma}_0$ is large, a reliable result may not be given, because large $\hat{\sigma}_0$ suggests that there are some large observational errors or some mistakes in the interpretation of seismograms. Although the distribution of $\hat{\sigma}_0$ does not follow the normal law and it is not clear what criterion is suitable in the present case, the cases of $\hat{\sigma}_0$ larger than 3.0 were omitted referring to the result in the next section.

Frequency distributions of standard errors of origin time, epicenter coordinates and focal depth are shown in Fig. 3a. The cases in which the standard error of the epicenter location is larger than 10.0 km, that of the depth is larger than 20 km or that of the origin time is larger than 2.0 sec were omitted, because they are considered to give inaccurate result.

The solutions obtained in good accuracy are listed in Table 2.

In the next place, x, y, z, t and v were calculated using the values of x, y, z and t obtained by the foregoing procedure as a starting point. Only 22 values of the velocity were obtained, but these values show large

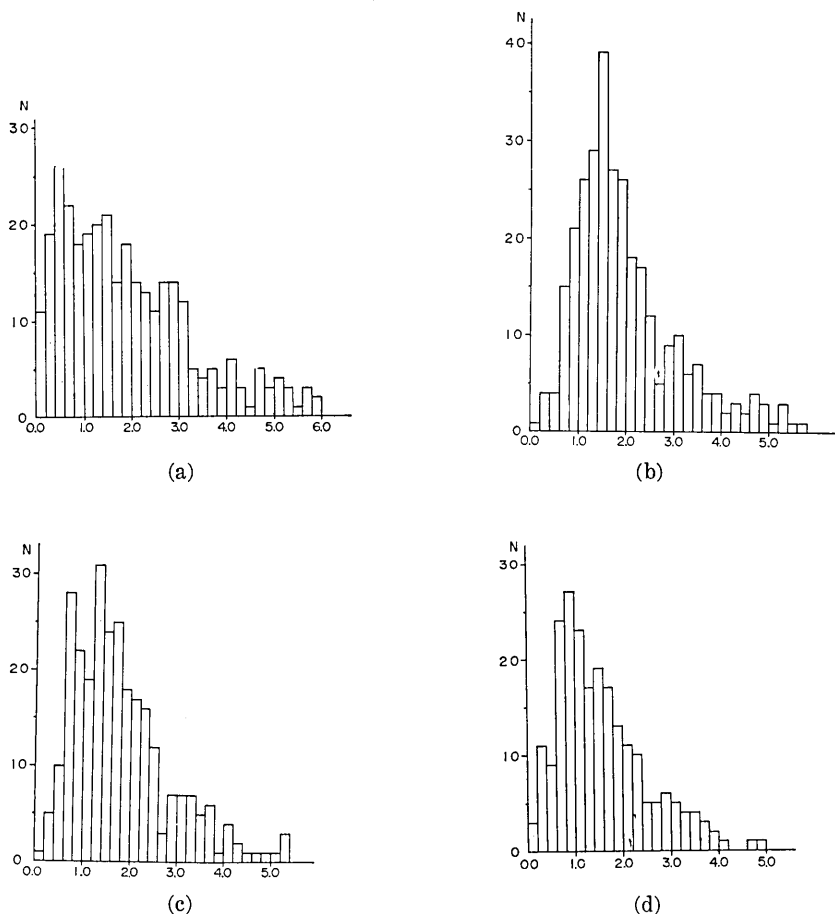

Fig. 2. Frequency distributions of estimates ($\hat{\sigma}_0$) of residuals with a unit weight.

$\hat{\sigma}_0=1.00$ corresponds to 0.1 sec for iP

- (a) The case in which t, x, y and z are calculated from P arrival time with V_p assumed at 6.0 km/s.
- (b) The case in which t, x, y and z are calculated from P and S arrival times with V_p assumed at 6.0 km/s and V_p/V_s at 1.732.
- (c) The case in which t, x, y, z and V_p are calculated from P and S arrival times with V_p/V_s assumed at 1.732.
- (d) The case in which t, x, y, z, V_p and V_p/V_s are calculated from P and S arrival times.

fluctuation and large standard error. Therefore the result obtained here is not adequate to discuss the velocity of the P wave. In some cases, noticeable discrepancies are found between hypocentral distances deter-

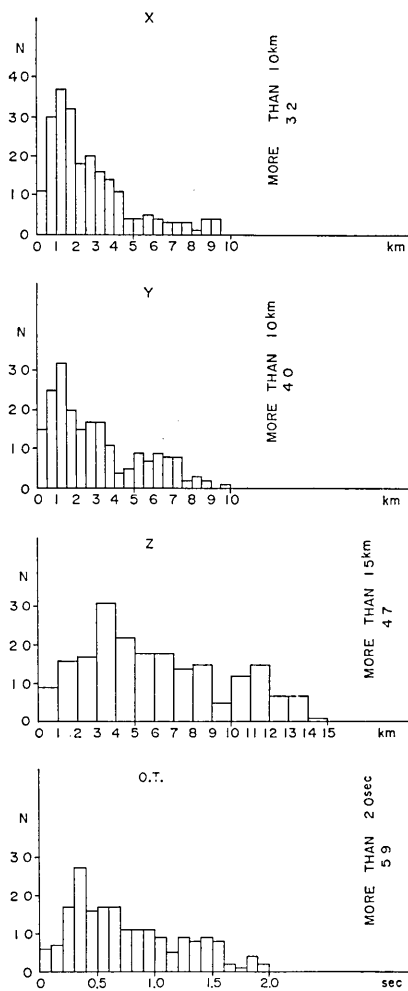

Fig. 3a. Frequency distributions of the standard errors of the epicenter location, origin time and focal depth determined from the arrival times of the *P* wave.

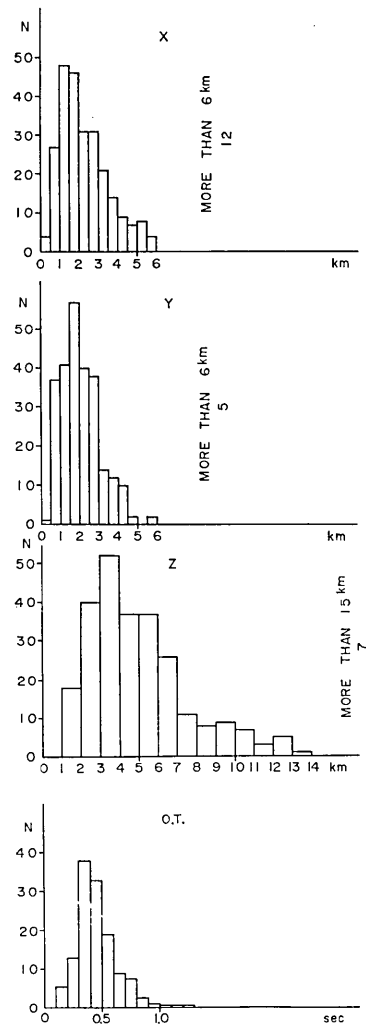

Fig. 3b. Frequency distributions of the standard errors of the origin time, epicenter location and focal depth determined from the arrival times of *P* and *S* waves.

mined by such procedure and *P-S* intervals at some stations. This fact suggests that slight observational errors cause large errors in hypocentral location when it is determined from only arrival times of the *P* wave.

3.2. Determination of origin times, epicenters and focal depths from arrival times of the P and S waves.

In order to avoid such difficulties as mentioned in the foregoing section, P - S intervals have been used by many seismologists.⁷⁾ Usually P - S intervals give reasonable hypocenters, because they give directly hypocentral distances. The use of only P - S intervals, however, does not allow determination of the origin time. Therefore, the author tried to use arrival times of both the P and S waves in a method similar to the previous section, adopting the following relation:

$$(3) \quad (x-x_i)^2 + (y-y_i)^2 + (z-z_i)^2 = \gamma^2 V_p^2 (t-t_{s_i})^2,$$

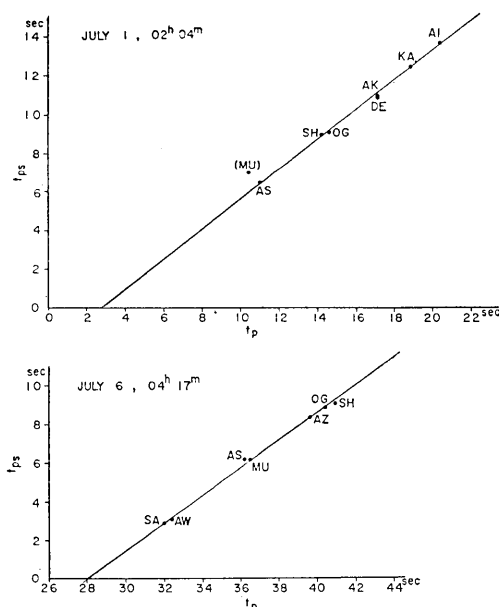

Fig. 4.

where $\gamma = V_s/V_p$ and t_{s_i} is the arrival time of the S wave at the i -th station.

On the assumption that $V_p = 6.0$ km/s and $1/\gamma = V_p/V_s = 1.732$, x , y , z and t were calculated for the shocks for which four or more arrival times of the P wave and three or more arrival times of the S wave were observed.

In order to find out misinterpretation of the S phase, t_p vs. t_{ps} diagrams (for example, Fig. 4) were drawn. On that diagram, the point (t_p, t_{ps}) should come on a straight line, if V_p/V_s is constant. The gradient of the line is $(V_p/V_s) - 1$

and the line intersects t_p axis at $t_p = t$. Therefore the origin time can be directly determined on the diagram.⁸⁾ Strictly speaking, V_p/V_s is not

S. MIYAMURA, "Local Earthquakes in Kii Peninsula, Central Japan. Part 4. —Location of Earthquakes by the Temporary Network of Stations near Wakayama—" (in Japanese), *Bull. Earthq. Res. Inst.*, **38** (1960), 71-112.

8) H. WATANABE and A. KUROISO, "Some Properties of Microearthquakes in the West of Kii Peninsula, Central Honshu, Japan" (in Japanese), *Zisin (Journ. Seism. Soc. Japan)*, [ii], **20** (1967), 180-191.

constant. The line, however, can be safely regarded as straight within several tens of kilometers of the epicenter. If there is a misinterpretation of the S phase, the point will deviate from this straight line. Therefore such data that the point on the diagram deviates from the line by more than 1 sec were omitted.

For about 400 cases, the solution of x, y, z and t converged. The frequency distribution of $\hat{\sigma}_0$ is shown in Fig. 2(b). The distribution seems to follow the normal law with a mean of 1.5. The cases in which $\hat{\sigma}_0$ are larger than 3.0 were omitted, considering that they probably contain some erroneous observational data.

In some 60 cases, the depth became negative in the course of iteration. In such cases, the depth was assumed to be 5 km, because the foci of such shocks are considered to be shallow. The frequency distribution of standard errors of x, y, z and t are shown in Fig. 3b. The standard

errors of x, y, z and t distribute around 1.5 km, 1.7 km, 3.5 km and 0.4 sec respectively and three-fourths of them distribute within the range of 3.1 km, 2.7 km, 6.4 km and 0.54 sec respectively. The accuracy is about twice higher than those determined from t_p only in the previous section. The results in which the standard errors are beyond 10 km with respect to epicenter and focal depth and 1.0 sec with respect to origin time were omitted, because such numerals can be considered to be unreliable.

Origin times, epicenter coordinates and focal depths of some 300 shocks determined in good accuracy are listed in Table 3.

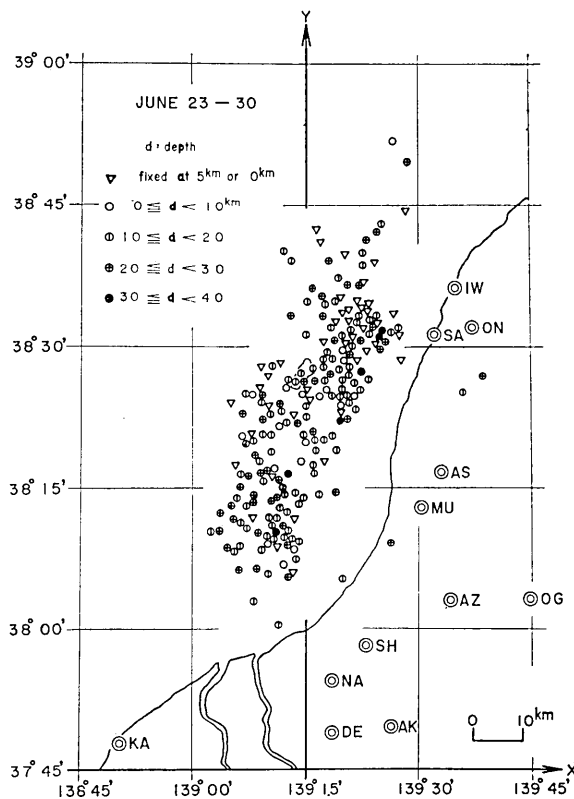

Fig. 5a.

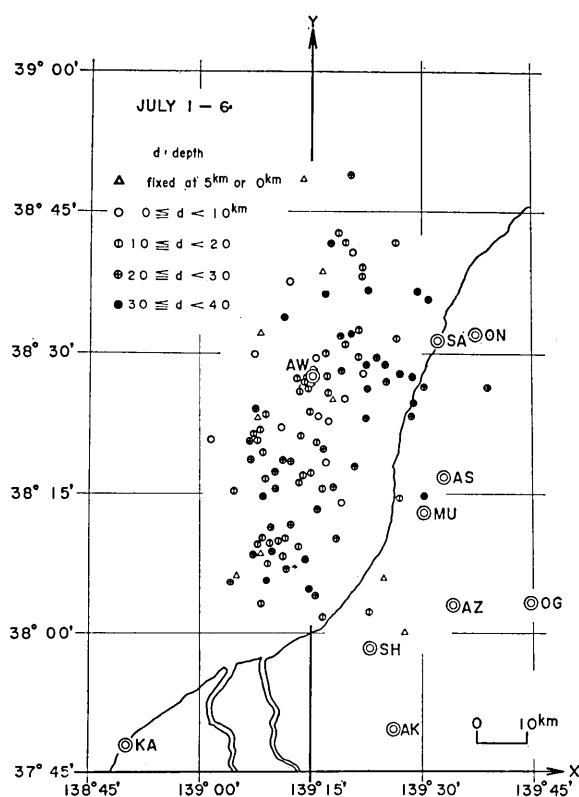

Fig. 5b.

shocks occurred in the period of seven and a half days following the main shock, during which as many as three-fourths of the total aftershocks which were detected by the JMA network in 45 days after the main shock occurred.¹¹⁾ Moreover epicenters in marginal region might

The epicentral distribution of aftershocks in Fig. 5 shows that the aftershock domain has an elliptical shape with longer axis lying in the direction N30°E-S30°W. This direction is approximately parallel to the axis of the geological structure in this region and also to the fractures and faults found on the island of Awashima and its surrounding sea bottom.⁹⁾

The epicenter of the main shock lies in the central part of the aftershock domain, in contrast with the common fact that the epicenter of the main shock lies on the border of the aftershock domain.¹⁰⁾

Fig. 5 does not include the epicenters of after-

not be accurately determined due to the limited distribution of observation points. However, the epicentral distribution obtained in this section is similar to the epicentral distribution of 208 larger aftershocks located by the JMA routine network¹²⁾ and may be safely regarded as the general pattern of the aftershock activity in the present case.

It is noted that few aftershocks occurred near the epicenter of the main shock and in a region 20 km distant northeastward from it, nevertheless many aftershocks were occurring in their surrounding area.

The distribution of focal depths in Fig. 7 shows that foci of aftershocks lie mostly at depths between 10 km and 22 km and few aftershocks appear to occur in places shallower than 10 km. This may be partly due to difficulty in determining depths of shallower shocks, but

12) *ibid.*, 3)

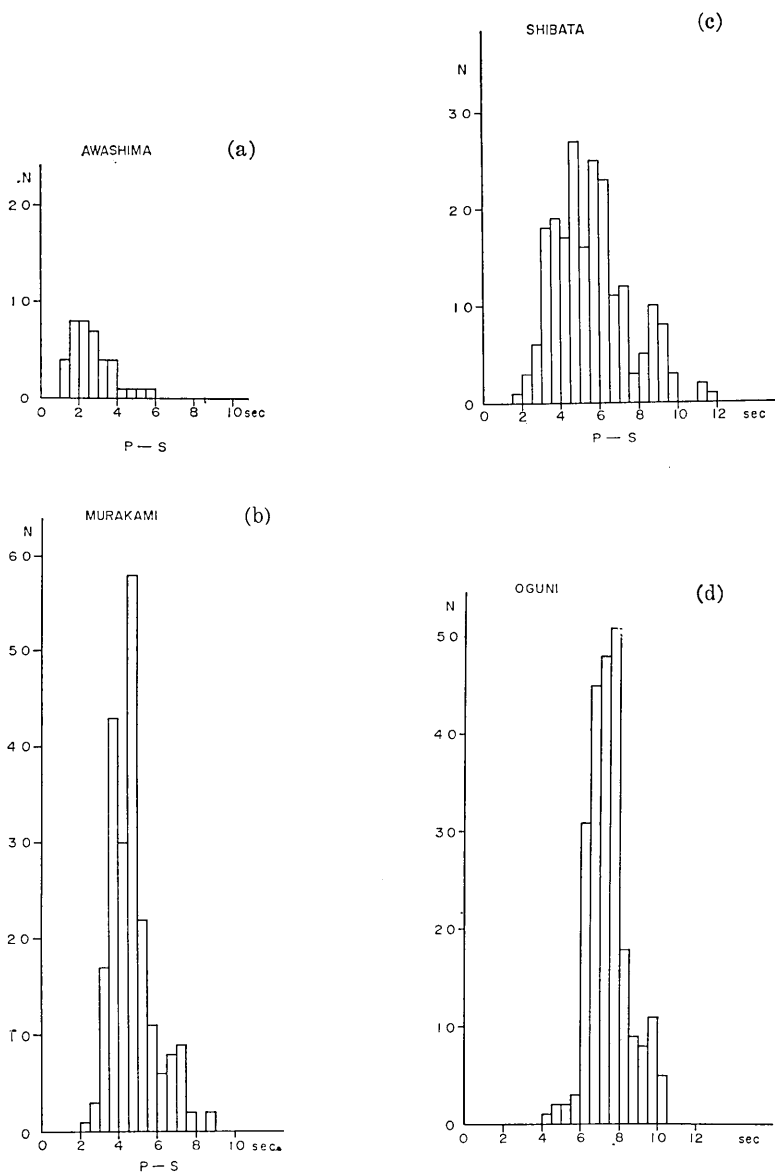

Fig. 8. Frequency distributions of the hypocentral distances from the stations, of which the data were used to determine the hypocenters. The abscissa is scaled as the $P-S$ interval, that is, the hypocentral distances divided by 8.196.

the fact that $P-S$ intervals shorter than 1.5 sec were rarely observed at Awashima, which lies in the midst of the aftershock area, supports

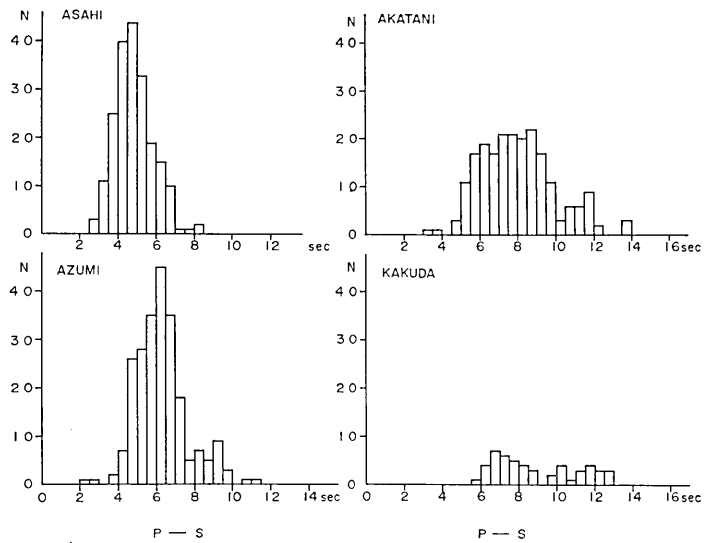

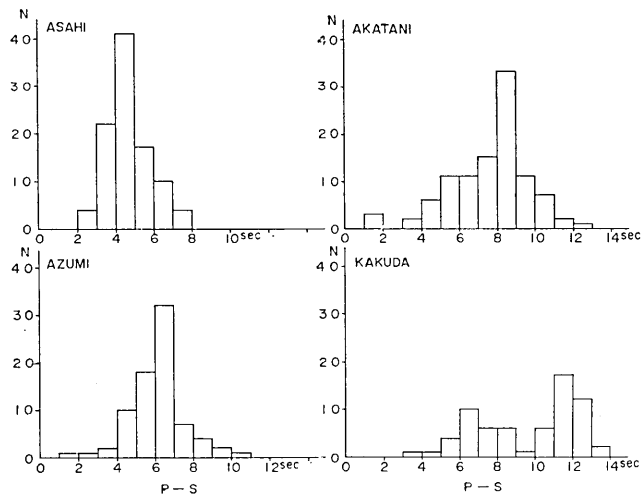

Fig. 8. (e)

Fig. 9. Distribution of observed $P-S$ intervals

the conclusion that few aftershocks occurred at depths shallower than 10 km. This may have some correlation with the fact that the focal depth of the main shock was 40 km.

In order to check the hypocentral distribution determined in this section, the frequency distribution of hypocentral distances from each

station was made as shown in Fig. 8. In the figure, the abscissa is scaled as the P - S interval, that is, the hypocentral distance divided by the Omori constant 8.196 calculated from $V_p=6.0$ km and $V_p/V_s=1.732$. Accordingly the figure corresponds to the frequency distribution of P - S intervals at the corresponding station indicated in Fig. 6 in the previous paper¹³⁾ and in Fig. 9. If the hypocentral distribution determined in this section gives general aspect, both the distributions should be the

same in shape. Therefore, the similarity between these distributions assures that the hypocentral distribution determined in this section represents the general aspect of the aftershock activity.

Epicenters of a group of shocks near Oguni, which might be independent from the aftershocks, were not determined.

In order to compare the results determined from t_p only with the results from t_p and t_s together, frequency distributions of the differences of the origin times, epicenter locations and focal depths determined in the two methods are shown in Fig. 10.

In a half of the cases, the results obtained by the two methods coincide with one another within a deviation of 0.5 sec for origin time, 2.2 km for epicenter and 4 km for depth. In some cases the two methods give results having larger discrepancy. In most cases, the result from combination of t_p and t_s seems to be more reliable, because hypocenters determined from only t_p is greatly affected by a slight observational error.

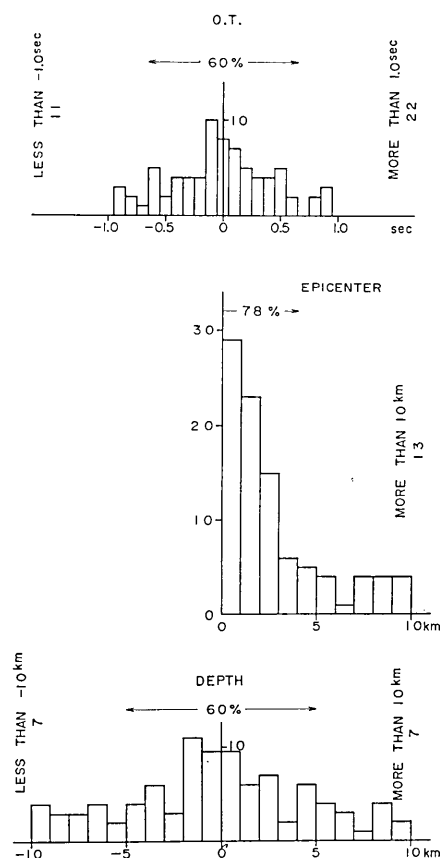

Fig. 10. Frequency distributions of the differences between the origin times, epicenter locations and focal depths determined from the arrival times of the P wave only and those determined from the arrival times of P and S waves together.

13) *ibid.*, 2)

3.3. The velocity of the P wave (V_p) and the ratio of velocity of the P wave to the S wave (V_p/V_s).

Next the velocity of the P wave as well as x, y, z and t were calculated from the same data on the assumption that V_p/V_s is 1.732. Some 250 solutions for the velocity of the P wave were obtained. The values of V_p and their standard error are shown in the column II in Table 3 and Fig. 11(a). The values of V_p with standard error exceeding 1.0 km/s were omitted in the table and in Fig. 11(a). The values of V_p calculated here were not determined from only t_p , but from both t_p and t_s using the relation $V_p/V_s=1.732$.

The ratio of the velocities of the P wave to S wave, in addition to x, y, z, t and V_p , were calculated on an assumption of a uniform half space for the shocks of which arrival times of S wave were observed at three or more stations. Some 180 solutions for V_p/V_s were obtained.

The values of V_p and V_p/V_s and their standard errors are shown in the column III in Table 3 and Figs. 11(b) and 12. The V_p with standard error exceeding 1.0 km/s and the V_p/V_s with standard error exceeding 0.1 were omitted in the table and in Figs. 11(b) and 12. In Fig. 12, the black parts of column indicate numbers of more reliable ones that

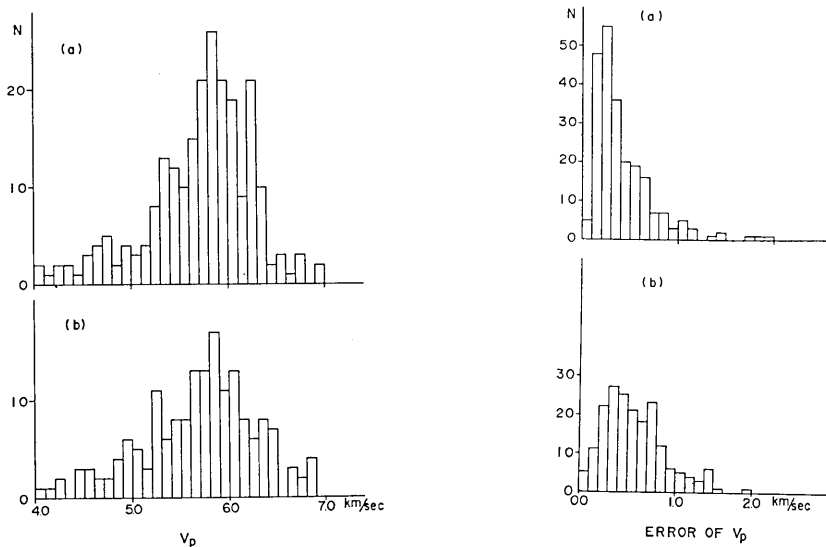

Fig. 11. Frequency distributions of the velocity of the P wave (V_p) determined from the arrival times of P and S waves and its standard error.

(a) V_p/V_s is assumed at 1.732.

(b) V_p/V_s is variable.

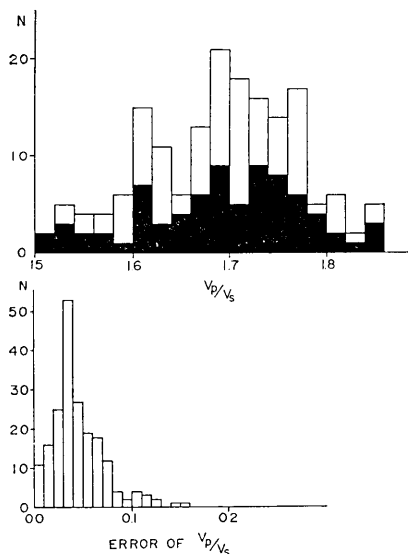

Fig. 12. Frequency distributions of the ratio of the velocities of P and S waves (V_p/V_s) and standard errors. Black parts indicate the values determined from the data including five or more S arrival times.

that obtained by putting V_p and V_p/V_s unknown.

were determined from data including five or more arrival times of the S wave.

The values of V_p and V_p/V_s are scattered widely. Such scattering seems to be of unreal existence and to have come from observational errors. The mean value of V_p obtained in this section is about 5.8 km/s and the mean value of V_p/V_s is about 1.70, both the values being slightly smaller than those assumed in the beginning. If calculation is carried out again on the basis that $V_p = 5.8$ km/s and $V_p/V_s = 1.700$,¹⁴⁾ a different epicentral distribution will be given. However, such recalculation was not tried, as the difference is expected to be very small.

The epicentral distribution obtained by giving suitable values to V_p and V_p/V_s has less deviation than

4. Conclusion and acknowledgement

Origin times, epicenters and focal depths of some 400 small aftershocks of the Niigata Earthquake were given with sufficient accuracy on the basis of data obtained by temporary observation carried out by Hokkaido University, Tohoku University, the Earthquake Research Institute of the University of Tokyo and the Japan Meteorological Agency.

Epicenters are difficult to be determined from only arrival times of the P wave of a small number of stations, while the use of arrival times of the P and S waves gives good results.

The present author hopes that the results offered in this paper will be useful for further investigation of the aftershocks.

The author expresses his gratitude to all the members who participated in the observational work and Prof. T. Hagiwara for his encouragement and valuable suggestions throughout this study.

Numerical computations were carried out on an OKITAC 5090 of the Data Processing Center of the University of Tokyo and on an HITAC 5020 of the Computation Center of the University of Tokyo.

12. 昭和 39 年 6 月 16 日新潟地震余震の発震時、震源位置の決定 ——新潟地震余震共同研究序報——

地震研究所 茅 野 一 郎

昭和 39 年 6 月 16 日の新潟地震の余震観測のため、北海道大学、東北大学、地震研究所、気象庁より、それぞれ、2 乃至 4 の臨時観測班が送られた。これらの観測班により得られた観測資料を総合して、震源の決定が行われた。

P 波の到達時刻のみを用いるときは、適当な解が得られないか、または誤差が著るしく大きくなる場合が少くないので、P 波及び S 波の到達時刻を併用して、約 400 個の余震の震源が求められた。半数は、誤差が、発震時で 0.4 秒、震央位置で約 2 km、深さで 3.5 km 以内である。

余震域は、N 30 E—S 30 W 方向に長軸をもち、長径約 100 km、短径約 50 km の楕円形の地域で、本震はほぼその中央に位置する。震源の深さは、大部分 10~22 km の範囲に集中している。

P 波の速度、P 波と S 波との速度比も求められた。この地域で、平均して、P 波の速度は 5.8 km/s、P 波と S 波との速度比は 1.70 である。
