21. *The Construction and Study of an Acceleration Seismograph.*

By TAKURO TAMARU.

1. *The Object of the present Seismograph.* It has been too difficult for the hitherto built seismograph to calculate the acceleration minutely from its record of displacement or velocity of the earth's movement. So I think it will be very useful to construct a seismograph capable of recording acceleration directly. The hitherto one, besides, has been nearly unstable in arrangement, incapable of recording the three dimensional movement by a single mass, full of obstruction on the proper oscillation, deflection of the index outside of the limit of the recording paper as the result of too great amplitude of oscillations and so on. The new seismograph will save all these defects.

2. *The General Structure.* It is composed of the main frame, the pendulum, and three sets of drums and indexes. The cast iron frame has the width and length of 42 cm., the height of 41 cm. The single mass of pendulum, which finds itself in the centre of frame has 40 kg. In the right, and in the front, we find two indexes which register the horizontal movement, and in the left, one which records the vertical movement. Each index touches on its respective drum, which rotates with the speed of 9 cm. per min., and draws the diagram during the whole day on a sheet of paper in each component. It will be costed about 500 Yen with its accessories (drums, clockworks, etc.).

3. *The General Characteristics.* The special arrangements and the general characteristics derived therefrom are the followings:

(i) Recording of Acceleration. It is our fundamental idea attaining the aimed record of acceleration, to arrange a pendulum with fairly great mass so as to move similarly as the earth, and to record the force between the pendulum and the frame sustaining it. This force, which is necessary to make the pendulum move samely with the earth, has a direct proportion to the acceleration of the earth's movement. If we aim only to record this force, we may well use strong springs in every direction—upwards and down wards, east and west, north and south. The deformation of the spring is therefore in proportion to the kinematic changes of the motion of the pendulum. The record thus obtained shows the acceleration. We will not, however, simply use a strong spring in holding the pendulum, for the sake of the fifth characteristics.

(ii) It can register the three dimensional movement using a single pendulum being connected with the same arrangement for each component.

(iii) It has a very stable equilibrium while the hitherto one has been nearly unstable.

(iv) Less influence of proper oscillation and thermal changes. It seems for an acceleration seismograph to have minute proper oscillations mixed within. It is, however, necessary to lessen the proper oscillation, when the period of the proper oscillation is not so small compared to that of the earth's shocks. This apparatus will have a special arrangement under the holder of the index, to absorb the proper oscillation. To lessen the thermal influence which may be given to the spring, the brass holding of the spring, the wire connecting the spring and the pendulum, the cast iron frame etc., we can make a preparatory calculation of the expansion coefficient of their material, and consequently neglect the thermal deformation of the apparatus as a seismograph.

(v) In order to get rid of the deflection of the index outside of the recording paper as the result of too great shocks, it has a special arrangement to restrict the index mo-

ton within a certain limit. In other words, we do not simply use strong springs in holding the pendulum, but the degree of deflection of the index is made to lessen according as the force increases, (the force necessary for making it movable samely with the earth) and when this force increases more and more, the index approaches near to a certain position asymptotically in a certain direction.

(vi) To lessen the effect of the friction at the end of the index when we register very small acceleration of a slow earth movement, we may efficiently attempt to join a tuning fork with the pendulum, which is constantly vibrated by electric current. Thus the end of the index always draws a curve having a certain width, and the middle line of the width will show the position of the index free from the frictional effects. The validity of this plan, however, depends on experiment.

(vii) The acceleration seismograph suffers less influence of the earth's tilting than the horizontal pendulum. Besides, the tilting appears enormously in the index in the latter, while it appears directly in the former. The tilting and the horizontal acceleration make entirely same action in the nature of the acceleration seismograph. But this is not the defect of this apparatus. Considering that in case of earthquake the body fixed on the earth (e. g., a building) also suffers the same action from tilting and horizontal acceleration. We may, therefore, neglect the tilting motion of the present apparatus as to be applied to every thing.

To make a record of feeble earthquakes having the period of several seconds we will need a pendulum of the weight several hundred or several thousand kgs. Else, we may either take a method of optical recording, or make the period of proper oscillation great, therewith connecting an arrangement which lessens the influence of friction. All these I hope for the future study.
